Abstract

I report on a numerical program for the evolution of parton distributions. The program uses the Mellin-transform method with an optimized contour. Due to this optimized contour the program needs only a few evaluations of the integrand and is therefore extremely fast. In addition, the program can also be used to reproduce the results of the x-space method.

PROGRAM SUMMARY

Title of program: partonevolution

Version: 1.0

Catalogue number:

Program obtained from: <http://www.fis.unipr.it/~stefanw/partonevolution>

E-mail: stefanw@fis.unipr.it

License: GNU Public License

Computers: all

Operating system: all

Program language: C++

Memory required to execute: negligible (1 MB)

Other programs called: none

External files needed: none

Keywords: Parton distributions, next-to-leading order evolution.

Nature of the physical problem: Parameterizations of parton distributions are usually given at a fixed input scale Q_0 . To be used in perturbative calculations, they have to be evolved numerically to the desired scale Q .

Method of solution: Inverse Mellin transform method.

Restrictions on complexity of the problem: None.

Typical running time: 10^{-2} s on a standard PC for an accuracy of 0.02%, see also sect. 5.

1 Introduction

Experiments at hadron colliders require apart from the hard scattering amplitudes, which can be calculated in perturbation theory, also the knowledge of the parton distributions functions (pdf's). Although these parton distribution functions parameterize the non-perturbative information, they depend on a factorization scale and the dependence on that scale can be calculated within perturbation theory. Usually parameterizations of parton distributions functions are given at a low input scale [1] - [3] and then evolved to the desired scale. At present the evolution kernel is known completely to next-to-leading order (NLO) [4] - [9]. The evolution has to be done numerically. There are two methods available: The first one consists in integrating numerically the evolution equations in x and in Q^2 and is called the x -space method. The second one first performs a Mellin-transform on the variable x [10, 11]. The evolution equations then factorize and can be solved analytically. Using this Mellin-transform method (or N -space method), leaves us with the task to evaluate the inverse Mellin transform numerically. In this paper I describe a numerical program, which uses an optimized integration contour in the complex N -plane in order to do the inverse Mellin transform. This method has been proposed by Kosower [12]. Using this method gives a fast and accurate program for the evolution of parton distributions. Although a variety of numerical evolution programs already exist (mainly within the x -space method) [13] - [22], they usually cannot compete in computation speed. The required CPU time becomes an issue if one tries to extend the analysis of experiments at hadron colliders in two important directions:

- Parton distributions with error-bars [23, 24]. The Tevatron data on the measurement of the one jet inclusive transverse energy has shown [25] that the method of obtaining parton distributions from “global fits” has reached its limits. Giele, Keller and Kosower [23, 24] have proposed a method to include uncertainties into the parton distributions. This method involves a functional integration over a set of parton distributions. With a set of pdf's containing 1000 or more parton distributions, the traditional approach of a pre-calculated grid containing the evolved parton distributions becomes inappropriate. Instead, one would need a program which allows to calculate the evolution on the fly. The program presented here allows one to do just that.
- Extension to NNLO. The calculation of the three-loop anomalous dimensions is currently under way [26, 27]. It is likely that the result will be rather lengthy. The computational cost of evaluating the anomalous dimensions will therefore be rather high, and one would like to minimize the number of function calls to the anomalous dimensions. The optimized contour employed in this program minimizes this number. Once the three-loop anomalous dimensions are known, the program can be extended in a straightforward way to include NNLO corrections.

The program is optimized for the N -space method, where one needs typically only four or five evaluations of the anomalous dimensions to obtain the evolution of a parton distribution with an accuracy of $2 \cdot 10^{-4}$. In addition, I also include an option to simulate the x -space evolution programs. x -space programs use a different truncation prescription and the results might differ numerically from the N -space approach. It should be noted, that both approaches are valid to next-to-leading order, the difference is formally of higher order. The x -space option is included

to allow an easy comparison with those programs, however it is not optimized. In technical terms, since no closed formula for the evolution operator in the singlet sector within the x -space approach is known, the evolution operator is approximated by a sequence of evolutions over a small interval. This slows down the program considerably. The N -space evolution method is therefore the recommended one, where the full performance of the program is obtained.

This paper is organized as follows. In section 2 I recall the basic formulae for the evolution of parton densities and sketch how to choose an optimized contour using the Mellin transform method. Section 3 gives an overview of the design of the program, while section 4 is of a more practical nature and describes how to install and use the program. In section 5 I compare the program with the reference results of Blümlein et al. [28, 29] and address issues like performance. A summary is provided in section 6. The appendix collects the formulae for the evolution operators.

2 Theoretical Background

The evolution equations for the parton distributions $f(x, Q^2)$ of the proton read

$$Q^2 \frac{\partial f(x, Q^2)}{\partial Q^2} = P(x, Q^2) \otimes f(x, Q^2), \quad (1)$$

where x stands for the nucleon's momentum fraction carried by the parton, $P(x, Q^2)$ is the Altarelli-Parisi evolution kernel, and $\otimes$ denotes the convolution

$$A(x) \otimes B(x) = \int_0^1 dy \int_0^1 dz \delta(x - yz) A(y) B(z). \quad (2)$$

Eq. (1) is understood to represent the quark non-singlet evolution as well as the coupled quark singlet and gluon evolution. In the latter case f is a two-component vector and $P(x, Q^2)$ a two-by-two matrix. Eq. (1) can be factorized by taking Mellin moments

$$A^z = \int_0^1 dx x^{z-1} A(x) \quad (3)$$

and one obtains

$$Q^2 \frac{\partial f^z(Q^2)}{\partial Q^2} = P^z(Q^2) \cdot f^z(Q^2). \quad (4)$$

Changing variables by using $a_s = \alpha_s(Q^2)/4\pi$ instead of $\ln Q^2$ as evolution variable one obtains

$$\frac{\partial f^z(Q^2)}{\partial a_s} = \frac{P^z(a_s)}{\beta(a_s)} f^z(Q^2), \quad (5)$$

where

$$\beta(a_s) = Q^2 \frac{\partial a_s}{\partial Q^2} \quad (6)$$

is the beta function for the strong coupling. Up to now, the evolution kernel is known completely only to next-to-leading order:

$$P^z(Q^2) = a_s P_0^z + a_s^2 P_1^z + O(a_s^3). \quad (7)$$

To this order, the beta function is given by

$$\beta(a_s) = -\beta_0 a_s^2 - \beta_1 a_s^3 + O(a_s^4). \quad (8)$$

Inserting eq. (7) and eq. (8) into eq. (5) and expanding the r.h.s in a_s one obtains

$$\frac{\partial f^z(Q^2)}{\partial a_s} = -\frac{1}{\beta_0 a_s} \left[P_0^z + a_s \left(P_1^z - \frac{\beta_1}{\beta_0} P_0^z \right) \right] f^z(Q^2). \quad (9)$$

Solutions of eq. (9) are referred to as “N-space” solutions, since this is the standard approach within the N-space method. One the other hand, one might defer from inverting the power series in the denominator on the r.h.s of eq. (5) and to solve eq. (5) directly. To NLO, this amounts to solving

$$\frac{\partial f^z(Q^2)}{\partial a_s} = -\frac{(P_0^z + a_s P_1^z)}{a_s (\beta_0 + \beta_1 a_s)} f^z(Q). \quad (10)$$

Solutions of eq. (10) are referred to as “x-space” solutions, again since this corresponds to the usual procedure within the x-space method. Eq. (9) and eq. (10) differ by terms which are formally of higher order in a_s , and solutions to both equations are therefore considered accurate to next-to-leading order, although they might differ numerically.

In addition there are different common practices on how to calculate a_s at the scale Q^2 . At NLO $a_s(Q^2)$ can be found from the solution of the equation

$$\frac{1}{a_s} - \frac{\beta_1}{\beta_0} \ln \left(\beta_1 + \frac{\beta_0}{a_s} \right) - \beta_0 L = 0, \quad (11)$$

where $L = \ln \frac{Q^2}{\Lambda_{QCD}^2}$. This equation has to be solved numerically, and solutions of eq. (11) are referred to as “exact” NLO solutions. On the other hand it is common practice to view a_s as a power series in $1/L$ and to use

$$a_s = \frac{1}{\beta_0 L} \left(1 - \frac{\beta_1}{\beta_0^2} \frac{\ln L}{L} \right) \quad (12)$$

to calculate a_s at the scale Q^2 . Solutions of eq. (12) are referred to as “truncated in $1/L$ ” solutions. Again, the numerical values might differ for solutions of eq. (11) and eq. (12). It should be mentioned that the integration constant Λ_{QCD} appearing in eq. (11) is not identical to the integration constant of the same name in eq. (12), e.g. fixing a_s at a scale like m_Z^2 and solving eq. (11) and eq. (12) for Λ_{QCD} will yield two different numerical values. Each value has to be used in conjunction with the equation from which it was obtained.

Eq. (9) and eq. (10) are formally solved by the introduction of an evolution operator E^z :

$$f^z(Q^2) = E^z(a_s(Q^2), a_s(Q_0^2)) f^z(Q_0^2) \quad (13)$$

Furthermore, there is yet another truncation method used in the literature: Within this method one does not perform the change of the evolution variable from Q^2 to a_s , but one substitutes the truncated solution eq. (12) for a_s into eq. (4). This amounts to solving

$$Q^2 \frac{\partial f^z(Q^2)}{\partial Q^2} = \left(\frac{1}{\beta_0 L} \left(1 - \frac{\beta_1 \ln L}{\beta_0^2 L} \right) P_0^z + \frac{1}{\beta_0^2 L^2} \left(1 - \frac{\beta_1 \ln L}{\beta_0^2 L} \right)^2 P_1^z \right) f^z(Q^2). \quad (14)$$

I will refer to solutions of eq. (14) as “x-space and truncated in $1/L$ ” solutions. Again, this equation is formally solved by an evolution operator, which now depends on Q^2 and Q_0^2 instead of $a_s(Q^2)$ and $a_s(Q_0^2)$:

$$f^z(Q^2) = \hat{E}^z(Q^2, Q_0^2) f^z(Q_0^2) \quad (15)$$

Formulae for the evolution operators corresponding to the various truncation prescriptions are collected in the appendix. The evolved parton distributions in x-space are then obtained by an inverse Mellin transformation:

$$f(x, Q^2) = \frac{1}{2\pi i} \int_C dz x^{-z} f^z(Q^2). \quad (16)$$

Here, the contour C runs to the right of all singularities of the integrand.

The parton distributions are usually parametrized at the input scale Q_0^2 in a form like

$$x f(x, Q_0^2) = \sum_i A_i x^{\alpha_i} (1-x)^{\beta_i} \quad (17)$$

with Mellin transform

$$f^z(Q_0^2) = \sum_i A_i B(z + \alpha_i - 1, 1 + \beta_i), \quad (18)$$

where $B(x, y)$ is Euler’s beta function. Dropping from now on the arguments Q^2 and Q_0^2 our task is to evaluate the integral

$$I = \text{Re} \frac{1}{\pi i} \int_{C_s} dz E^z F(z), \quad (19)$$

$$F(z) = x^{-z} \sum_i A_i B(z + \alpha_i - 1, 1 + \beta_i),$$

where complex conjugation has been used to replace the contour C by C_s , starting at the real axis, right to the right-most pole and running upwards to infinity. In the singlet case $F(z)$ and A_i are vectors and E^z is a matrix. The most efficient way to solve this problem is to choose a contour in such a way that the integrand can very well be approximated by some set of orthogonal polynomials. The method is due to Kosower [12]. It uses a parabolic contour, completely determined by the parton distribution at the original scale Q_0^2 and evaluates the integral by a Gauss-Laguerre quadrature formula. With this method a few (e.g. four or five) evaluations of the integrand are sufficient to evaluate the integral to very high precision (e.g. to an accuracy of 0.02 %).

I shortly review this method for the non-singlet case. The contour of integration is given by

$$z(u) = z_0 + ic_2 \sqrt{u} + \frac{1}{2} c_2^2 c_3 u, \quad u = 0 \dots \infty, \quad (20)$$

where z_0 is the minima of the function $F(z)$ on the real axis right to the rightmost pole of $F(z)$. The parameters c_2 and c_3 are given by

$$c_2 = \sqrt{\frac{2F(z_0)}{F''(z_0)}}, \quad c_3 = \frac{F'''(z_0)}{3F''(z_0)}. \quad (21)$$

$F'(z)$, $F''(z)$ and $F'''(z)$ are the first three derivatives of $F(z)$ with respect to z . For the parameterization eq. (17) they are given by

$$\begin{aligned} F' &= \sum_i G'_i F_i, \\ F'' &= \sum_i (G''_i + G_i'^2) F_i, \\ F''' &= \sum_i (G'''_i + 3G''_i G'_i + G_i'^3) F_i, \end{aligned} \quad (22)$$

where $F_i = x^{-z} A_i B(z + \alpha_i - 1, 1 + \beta_i)$ and

$$\begin{aligned} G_i &= \ln(x^{-z} B(z + \alpha_i - 1, 1 + \beta_i)), \\ G'_i &= -\ln x + \psi(z + \alpha_i - 1) - \psi(z + \alpha_i + \beta_i), \\ G''_i &= \psi'(z + \alpha_i - 1) - \psi'(z + \alpha_i + \beta_i), \\ G'''_i &= \psi''(z + \alpha_i - 1) - \psi''(z + \alpha_i + \beta_i). \end{aligned} \quad (23)$$

Here, ψ , ψ' and ψ'' are polygamma functions. With this parameterization one obtains for the integral eq. (19):

$$I = \frac{c_2}{2\pi} \int_0^\infty \frac{du}{\sqrt{u}} e^{-u} \operatorname{Re} \left[e^u (1 - ic_2 c_3 \sqrt{u}) E^{z(u)} F(z(u)) \right]. \quad (24)$$

The function $u^{-1/2} e^{-u}$ is the weight function of the Laguerre polynomials $L_k^{-1/2}(x)$ and the integral can be approximated by a Gauss-Laguerre quadrature formula:

$$I \approx \frac{c_2}{2\pi} \sum_{j=1}^k w_j \operatorname{Re} \left[e^{u_j} (1 - ic_2 c_3 \sqrt{u_j}) E^{z(u_j)} F(z(u_j)) \right]. \quad (25)$$

Here, u_j are the zeros of $L_k^{-1/2}(x)$ and the weights w_j are given by

$$w_j = \frac{\Gamma(n + \frac{1}{2})}{n!(n+1)^2} \frac{u_j}{\left(L_{k+1}^{-1/2}(u_j) \right)^2}. \quad (26)$$

In the singlet case one has a two-component vector given by the quark singlet combination Σ^z and the gluon distribution G^z . There will be strong mixing already for moderate evolution in Q^2 , since Σ^z and G^z are not eigenfunctions of the evolution kernel. One might be tempted to work in a basis of eigenfunctions of the leading-order evolution kernel and to extend the method discussed above to these eigenfunctions, eventually choosing two different contours for the two eigenfunctions. However this approach faces two problems: First of all, one of the two eigenfunctions usually does not have a minimum on the real axis on the right of the rightmost

pole. Secondly, by using different contours for the two components one is forced to keep track of branch cut crossings, a task one would like to avoid. It is therefore better to use a single contour for both components, although it might not be the optimal one for both components. In the singlet sector the contour is chosen as follows (this differs from the original proposition of Kosower): z_0 is chosen as the minimum of the sum of the Σ^z - and the G^z -component. I then diagonalize the leading-order evolution kernel at z_0 :

$$\begin{pmatrix} e_1^z \\ e_2^z \end{pmatrix} = \begin{pmatrix} -\gamma_{0,qg}(z_0) & \gamma_{0,qg}(z_0) - \lambda_-(z_0) \\ \gamma_{0,gg}(z_0) - \lambda_+(z_0) & -\gamma_{0,qg}(z_0) \end{pmatrix} \begin{pmatrix} \Sigma^z \\ G^z \end{pmatrix}, \quad (27)$$

where the eigenvalues $\lambda_{\pm}$ are given by

$$\lambda_{\pm}(z_0) = \frac{1}{2} \left[\gamma_{qq}^{(0)}(z_0) + \gamma_{gg}^{(0)}(z_0) \pm \sqrt{\left(\gamma_{gg}^{(0)}(z_0) - \gamma_{qq}^{(0)}(z_0) \right)^2 + 4\gamma_{qg}^{(0)}(z_0)\gamma_{gq}^{(0)}(z_0)} \right]. \quad (28)$$

Note that any z -dependence in eq. (27) is only due to Σ^z or G^z , z_0 appearing in the anomalous dimensions is a fixed parameter. Strictly speaking the eigenvectors of eq. (27) are only eigenvectors at the point $z = z_0$ of the leading-order evolution kernel. I then take e_1^z to determine c_2 and c_3 and integrate both components with this contour. To compensate for the fact that z_0 is not necessarily the minimum of e_1^z , the formula eq. (21) is replaced by

$$c_2 = \sqrt{\frac{2F(z_0)F''(z_0)}{F''(z_0)^2 - F'(z_0)F'''(z_0)}}, \quad (29)$$

which takes into account corrections due to the fact, that the contour does not start from a minimum of $F(z)$ (e.g. $F'(z_0) \neq 0$). The reasons why this works is that in the cases of interest e_1^z is roughly the sum of Σ^z and G^z and so z_0 is approximately optimal for e_1^z . The other component e_2^z is roughly the difference and numerically therefore smaller.

3 Design of the program

The program is written in C++. All classes and functions are defined in the namespace pdf. The parameterization of a parton distribution at the initial scale Q_0^2 is represented by the class partondistribution. A partondistribution is constructed as follows:

```
// u-valence CTEQ 4M
int n = 2;
double Q0 = 1.6;
double A_u[2] = { 1.344, 1.344*6.402};
double alpha_u[2] = { 0.501, 0.501+0.873 };
double beta_u[2] = { 3.689, 3.689 };
int eta = -1;

partondistribution uvalence =
    partondistribution(n,Q0,A_u,alpha_u,beta_u,eta);
```

This corresponds to the parameterization

$$x u_v(x, Q_0^2) = 1.344 x^{0.501} (1-x)^{3.689} (1 + 6.402 x^{0.873}) \quad (30)$$

at the initial scale $Q_0 = 1.6$ GeV. Valence like distributions need to have $\eta = -1$ explicitly in the constructor. For distributions which correspond to $\eta = 1$ (e.g. distributions in the singlet sector or non-singlet non-valence distributions like $(u + \bar{u}) - (d + \bar{d})$), the η -parameter can be dropped.

This partondistribution can be evolved to a scale Q by calling the function `evolve_nonsinglet`:

```
// evolution to 10 GeV for x = 0.01
double Q = 10.0;
double x = 0.01;

double u_v = evolve_nonsinglet(uvalence, Q, x);
```

The function `evolve_nonsinglet` is just an entry point and the job is passed to the function `evolve_nonsinglet_5`, which performs a Gauss-Laguerre quadrature with 5 points. In addition there are functions `evolve_nonsinglet_3`, `evolve_nonsinglet_10`, `evolve_nonsinglet_20` and `evolve_nonsinglet_30`, corresponding to quadrature formulae with 3, 10, 20 and 30 points. These functions can be selected by passing an additional argument to `evolve_nonsinglet`, e.g.

```
// evolution using a 10-point quadrature formula
double u_v = evolve_nonsinglet(uvalence, Q, x, 10);
```

will call the function `evolve_nonsinglet_10`.

In the singlet sector evolution is done with the help of the function `evolve_singlet`:

```
// singlet evolution
vector_d singlet = evolve_singlet(Sigma, Gluon, Q, x);

double s = singlet[0];
double g = singlet[1];
```

`Sigma` and `Gluon` are of type `partondistribution` and represent the parameterization of the quark singlet combination and the gluon distribution, respectively. The evolution function returns a two-component vector, with the evolved quark singlet distribution as first component and the evolved gluon distribution as second component. In C and C++ subscription of arrays starts at zero. As in the non-singlet case the function `evolve_singlet` is just an entry point, calling `evolve_singlet_5`. Again, there are functions using quadrature formulae with 3, 5, 10, 20 and 30 points.

In addition there are the classes `evolutionkernel` and `alpha_strong`. The class `evolutionkernel` has a static data member method, which allows one to select the truncation method, e.g.

```
// select truncation method for evolution kernel
evolutionkernel::method = evolutionkernel::N_space;
```

will perform the evolution according to eq. (9). Other choices are `evolutionkernel::x_space` and `evolutionkernel::x_space_truncate_in_one_over_L`, corresponding to evolution according to eq. (10) and eq. (14), respectively.

In a similar way, the class `alpha_strong` has a static data member method, which allows one to select the truncation method for α_s , e.g.

```
// select truncation method for alpha_strong
alpha_strong::method = alpha_strong::truncate_in_one_over_L;
```

will use formula eq.(12), whereas the choice `alpha_strong::exact` will use eq. (11). In addition the user should set the flavor thresholds and the values of Λ_{QCD} for the different number of flavors, as for example in

```
// define values for alpha_strong (in GeV)
alpha_strong::charm_threshold = 1.3;
alpha_strong::bottom_threshold = 4.7;

alpha_strong::lambda_3 = 0.374;
alpha_strong::lambda_4 = 0.327;
alpha_strong::lambda_5 = 0.226;
```

Other classes of general interest provided by the package are the class `complex_d` corresponding to complex numbers with double precision as well as the templates `vector_template<class T>` and `matrix_template<class T>`. The specializations `vector_d`, `vector_c`, `matrix_d` and `matrix_c` define vectors and matrices with real or complex entries in double precision.

4 How to Use the Library

In this section I give indications how to install and use the program library. Compilation of the package will build a (shared) library called `libpartonevolution`. The user will then link his own programs against the library.

4.1 Installation

The program library can be obtained from

```
http://www.fis.unipr.it/~stefanw/partonevolution
```

After unpacking, the library for the evolution of parton distributions is build by issuing the commands

```
./configure
make
make install
```

There are various options which can be passed to the configure script, an overview can be obtained with `./configure --help`.

After installation, the shell script `partonevolution-config` can be used to determine the compiler and linker command line options required to compile and link a program with the `partonevolution` library. For example, `partonevolution-config --cppflags` will give the path to the header files of the library, whereas `partonevolution-config --libs` prints out the flags necessary to link a program against the library.

4.2 Writing programs using the library

Once the library is build and installed, it is ready to be used. Here is a small example program, which defines a parameterization at the scale $Q_0 = 2$ GeV and calls the evolution routine for $Q = 10$ GeV and $x = 0.01$.

```
#include <iostream>
#include "partonevolution/partonevolution.h"

int main()
{
    using namespace pdf;

    // select truncation methods
    alpha_strong::method = alpha_strong::truncate_in_one_over_L;
    evolutionkernel::method = evolutionkernel::N_space;

    // define a toy model with 4 flavors
    alpha_strong::charm_threshold = 0.0;
    alpha_strong::bottom_threshold = 1E10;
    alpha_strong::lambda_4 = 0.250;

    // define a parton distribution
    double Q0 = 2.0;
    double A_u[1] = { 35/16. };
    double alpha_u[1] = { 0.5 };
    double beta_u[1] = { 3.0 };
    int eta = -1;

    partondistribution f =
        partondistribution(1,Q0,A_u,alpha_u,beta_u,eta);

    // evolution
    double Q = 10.0;
    double x = 0.01;

    double res = evolve_nonsinglet(f,Q,x);

    // print out result
    cout << "x*f(x,Q^2) = " << x*res << endl;
}
```

After compilation and linking against the partonevolution library, one obtains an executable, which will print out

$x*f(x, Q^2) = 0.247242$

This program defines the u_v -distribution

$$xu_v(x, Q_0^2) = \frac{35}{16}x^{0.5}(1-x)^{3.0} \quad (31)$$

of the toy model of ref. [29]. The numerical difference of our value with the value 0.24723 quoted in ref. [29] is well below the estimated accuracy given in ref. [29].

4.3 Documentation

The complete documentation of the program is inserted as comment lines in the source code. The documentation can be extracted from the sources with the help of the documentation system “doxygen” [30]. The program “doxygen” is freely available. Issuing in the top-level build directory for the partonevolution library the commands

```
doxygen Doxyfile
```

will create a directory “reference” with the documentation in html and latex format.

5 Checks and performance

In this section I compare the results of our program with the reference results of Blümlein et al. [29]. The authors of ref. [29] define a toy model, consisting of four active flavors with $\Lambda_{QCD}^{(4)} = 250\text{MeV}$. At the input scale $Q_0^2 = 4\text{GeV}^2$ they take the initial parton distributions as follows:

$$\begin{aligned} xu_v &= A_u x^{0.5} (1-x)^3, & xd_v &= A_d x^{0.5} (1-x)^4, \\ xS &= A_S x^{-0.2} (1-x)^7, & xg &= A_g x^{-0.2} (1-x)^5, \\ xc &= 0, & x\bar{c} &= 0. \end{aligned} \quad (32)$$

The sea S is taken to be $SU(3)_{\text{flavor}}$ -symmetric and to carry 15% of the nucleon’s momentum at the input scale. This, together with the usual flavor- and momentum sum rules, fixes the constants A_u, A_d, A_S and A_g . The sea is related to the quark singlet distribution

$$\Sigma = \sum_{q=u,d,\dots} (q + \bar{q}) \quad (33)$$

by

$$S = \Sigma - u_v - d_v. \quad (34)$$

They provide a table with numerical results for the evolved parton distributions at the scale $Q^2 = 100\text{GeV}^2$. They have estimated the numerical accuracy of their results to be 0.02%. I have compared the program with the contents of table 1 of [29]. Using a 5-point quadrature formula the results of the program agree with the numbers presented there within the indicated estimated accuracy (0.02%), with some exceptions for the charm distribution and the singlet case for small values of x . Using a 10-point quadrature formula for those cases will lead to results within the 0.02% uncertainty margin. I have compared both the x -space solution (upper part of the table 1 in ref. [29], corresponding to solutions of eq. (14)) as well as the N -space solution (lower part of table 1 in ref. [29], corresponding to solutions of eq. (9) in combination with eq. (12) for the strong coupling).

Finally, I would like to give some indication on the required CPU time. The evolution of a non-singlet parton distribution with a 5-point Gauss-Laguerre quadrature formula takes about

$1.3 \cdot 10^{-3}$ s on a standard PC (Athlon, 1.6 GHz). The singlet evolution requires the evaluation of four anomalous dimensions. In addition there is some overhead for vector and matrix arithmetic. The singlet evolution is therefore more expensive in terms of CPU time. The evolution of the singlet combination takes about $6 \cdot 10^{-3}$ s, again with a 5-point Gauss-Laguerre quadrature formula on the same PC. These numbers apply to the N-space method. Simulating the x-space evolution method, the evolution of a non-singlet parton distribution with a 5-point Gauss-Laguerre quadrature formula takes about $1.3 \cdot 10^{-3}$ s. In the singlet sector, the evolution kernel has to be approximated by evolutions over small intervals. Subdividing the evolution interval into 1000 subintervals, the evolution of the singlet combination takes about $270 \cdot 10^{-3}$ s, again with a 5-point Gauss-Laguerre quadrature formula on the same PC.

6 Summary

In this paper I described the program library “partonevolution”. This library can be used to evolve parton distributions given by parameterizations at a scale Q_0 to the desired scale Q . The program uses the Mellin transform method with an optimized contour. Due to this optimized contour the program needs only a few evaluations of the anomalous dimensions and is therefore extremely fast. The library is therefore suited to be used in analysis involving parton distributions with errors, where a functional integration over a set of pdf’s is needed. Furthermore, once the three-loop anomalous dimensions are known, the extension of the algorithms to NNLO is straightforward. In addition, the program can also be used to simulate x-space evolution programs.

A Evolution operators

In this appendix the formulae for the evolution operators are collected. I start with the N-space method. The evolution operator, which solves eq. (9) is given in the non-singlet case by [7, 11]

$$E_{\eta}^z(a_s(Q^2), a_s(Q_0^2)) = \left(\frac{a_s(Q^2)}{a_s(Q_0^2)} \right)^{\frac{\gamma_0^z}{2\beta_0}} \left[1 + \frac{a_s(Q^2) - a_s(Q_0^2)}{2\beta_0} \left(\gamma_1^z(\eta) - \frac{\beta_1}{\beta_0} \gamma_0^z \right) \right]. \quad (35)$$

Here, $\eta = -1$ corresponds to the combinations $q - \bar{q}$, while $\eta = +1$ should be used for the non-singlet combinations like $(u + \bar{u}) - (d + \bar{d})$. I have expressed the evolution operator in terms of the anomalous dimensions γ_0^z and γ_1^z , which are related to the coefficients of the evolution kernel by $P_i^z = -\frac{1}{2}\gamma_i^z$. The explicit expressions for the anomalous dimensions can be found in [6]. For the singlet case one finds [7, 11]:

$$E^z(a_s(Q^2), a_s(Q_0^2)) = \left(\frac{a_s(Q^2)}{a_s(Q_0^2)} \right)^{\frac{\lambda_-^z}{2\beta_0}} \left[P_-^z + \frac{a_s(Q^2) - a_s(Q_0^2)}{2\beta_0} P_-^z \gamma^z P_-^z - \left(a_s(Q_0^2) - a_s(Q^2) \left(\frac{a_s(Q^2)}{a_s(Q_0^2)} \right)^{\frac{\lambda_+^z - \lambda_-^z}{2\beta_0}} \right) \frac{P_-^z \gamma^z P_+^z}{2\beta_0 + \lambda_+^z - \lambda_-^z} \right] + (+ \leftrightarrow -) \quad (36)$$

with

$$\begin{aligned}
\gamma^z &= \gamma_1^z - \frac{\beta_1}{\beta_0} \gamma_0^z, \\
\lambda_{\pm}^z &= \frac{1}{2} \left(\gamma_{0,qq}^z + \gamma_{0,gg}^z \pm \sqrt{(\gamma_{0,gg}^z - \gamma_{0,qq}^z)^2 + 4\gamma_{0,qg}^z \gamma_{0,gq}^z} \right), \\
P_{\pm}^z &= \pm \frac{1}{\lambda_+^z - \lambda_-^z} (\gamma_0^z - \lambda_{\mp}^z).
\end{aligned} \tag{37}$$

The evolution operator solving eq. (10) (e.g. “x-space method”) reads in the non-singlet sector [12]

$$E_{\eta}^z(a_s(Q^2), a_s(Q_0^2)) = \left(\frac{a_s(Q^2)}{a_s(Q_0^2)} \right)^{\frac{\gamma_0^z}{2\beta_0}} \left(\frac{\beta_0 + \beta_1 a_s(Q^2)}{\beta_0 + \beta_1 a_s(Q_0^2)} \right)^{\frac{\gamma^z(\eta)}{2\beta_1}}. \tag{38}$$

In the singlet case no closed form is known and the evolution operator has to be obtained as a sequence of evolutions over a small interval:

$$E^z(a_s(Q^2), a_s(Q_0^2)) = E^z(a^{(n)}, a^{(n-1)}) E^z(a^{(n-1)}, a^{(n-2)}) \dots E^z(a^{(1)}, a^{(0)}), \tag{39}$$

where $a^{(j)} = a_s(Q_0^2) + (a_s(Q^2) - a_s(Q_0^2)) j/n$. In a small interval the evolution operator for the singlet case can be approximated by [12]

$$\begin{aligned}
&E^z(a_s(Q^2), a_s(Q_0^2)) \\
&= \left(\frac{a_s(Q^2)}{a_s(Q_0^2)} \right)^{\frac{\lambda_-^z}{2\beta_0}} \left[P_-^z + \frac{1}{2\beta_1} \ln \left(\frac{\beta_0 + \beta_1 a_s(Q^2)}{\beta_0 + \beta_1 a_s(Q_0^2)} \right) P_-^z \gamma^z P_-^z + \frac{P_-^z \gamma^z P_+^z}{2\beta_0 + \lambda_+^z - \lambda_-^z} \right. \\
&\quad \left(a_s(Q^2) \left(\frac{a_s(Q^2)}{a_s(Q_0^2)} \right)^{\frac{\lambda_+^z - \lambda_-^z}{2\beta_0}} {}_2F_1 \left(1, 1 + \frac{\lambda_+^z - \lambda_-^z}{2\beta_0}, 2 + \frac{\lambda_+^z - \lambda_-^z}{2\beta_0}, -\frac{\beta_1}{\beta_0} a_s(Q^2) \right) \right. \\
&\quad \left. \left. - a_s(Q_0^2) {}_2F_1 \left(1, 1 + \frac{\lambda_+^z - \lambda_-^z}{2\beta_0}, 2 + \frac{\lambda_+^z - \lambda_-^z}{2\beta_0}, -\frac{\beta_1}{\beta_0} a_s(Q_0^2) \right) \right) \right] \\
&\quad + (+ \leftrightarrow -).
\end{aligned} \tag{40}$$

Finally, the evolution operator for eq. (14) (e.g. “x-space and truncated in $1/L$ ”) reads for the non-singlet case [12]

$$\begin{aligned}
\hat{E}_{\eta}^z(Q^2, Q_0^2) &= \left(\frac{L_0}{L} \right)^{\frac{\gamma_0^z}{2\beta_0}} \exp \left[-\frac{1}{2\beta_0^2} \left(\frac{1}{L_0} - \frac{1}{L} \right) \left(\gamma_1^z(\eta) - \frac{\beta_1}{\beta_0} \gamma_0^z \right) + \frac{\beta_1}{2\beta_0^3} \left(\frac{\ln L_0}{L_0} - \frac{\ln L}{L} \right) \gamma_0^z \right. \\
&\quad \left. + \frac{\beta_1}{4\beta_0^4} \left(\frac{1 + 2\ln L_0}{L_0^2} - \frac{1 + 2\ln L}{L^2} \right) \gamma_1^z(\eta) \right. \\
&\quad \left. - \frac{\beta_1^2}{54\beta_0^6} \left(\frac{2 + 6\ln L_0 + 9\ln^2 L_0}{L_0^3} - \frac{2 + 6\ln L + 9\ln^2 L}{L^3} \right) \gamma_1^z(\eta) \right],
\end{aligned} \tag{41}$$

where $L_i = \ln Q_i^2/\Lambda^2$. In the singlet case no closed form is known and the evolution operator is obtained as a sequence of evolutions

$$\hat{E}^z(Q^2, Q_0^2) = \hat{E}^z(Q_{(n)}^2, Q_{(n-1)}^2) \hat{E}^z(Q_{(n-1)}^2, Q_{(n-2)}^2) \dots \hat{E}^z(Q_{(1)}^2, Q_{(0)}^2), \tag{42}$$

where $Q_{(j)}^2 = Q_0^2 + (Q^2 - Q_0^2) j/n$. In a small interval the evolution operator for the singlet case is then approximated by [12]

$$\begin{aligned}
\hat{E}^z(Q^2, Q_0^2) = & \left(\frac{L_0}{L} \right)^{\frac{\lambda_-^z}{2\beta_0}} \left\{ P_-^z + P_-^z \left[-\frac{1}{2\beta_0^2} \left(\frac{1}{L_0} - \frac{1}{L} \right) \gamma^z + \frac{\beta_1}{2\beta_0^3} \left(\frac{\ln L_0}{L_0} - \frac{\ln L}{L} \right) \gamma_0^z \right. \right. \\
& + \frac{\beta_1}{4\beta_0^4} \left(\frac{1+2\ln L_0}{L_0^2} - \frac{1+2\ln L}{L^2} \right) \gamma_1^z \\
& - \frac{\beta_1^2}{54\beta_0^6} \left(\frac{2+6\ln L_0+9\ln^2 L_0}{L_0^3} - \frac{2+6\ln L+9\ln^2 L}{L^3} \right) \gamma_1^z \left. \right] P_-^z \\
& + P_-^z \gamma_1^z P_+^z \left[-\frac{1}{\beta_0(2\beta_0+\lambda_+^z-\lambda_-^z)} \left(\frac{1}{L_0} - \frac{1}{L} \left(\frac{L_0}{L} \right)^{\delta^z} \right) \right. \\
& + \frac{2\beta_1}{\beta_0^3(4\beta_0+\lambda_+^z-\lambda_-^z)} \left(\frac{\ln L_0}{L_0^2} - \frac{\ln L}{L^2} \left(\frac{L_0}{L} \right)^{\delta^z} \right) \\
& + \frac{2\beta_1}{\beta_0^2(4\beta_0+\lambda_+^z-\lambda_-^z)} \left(\frac{1}{L_0^2} - \frac{1}{L^2} \left(\frac{L_0}{L} \right)^{\delta^z} \right) \\
& - \frac{\beta_1^2}{\beta_0^5(6\beta_0+\lambda_+^z-\lambda_-^z)} \left(\frac{\ln^2 L_0}{L_0^3} - \frac{\ln^2 L}{L^3} \left(\frac{L_0}{L} \right)^{\delta^z} \right) \\
& - \frac{2\beta_1^2}{\beta_0^4(6\beta_0+\lambda_+^z-\lambda_-^z)} \left(\frac{\ln L_0}{L_0^3} - \frac{\ln L}{L^3} \left(\frac{L_0}{L} \right)^{\delta^z} \right) \\
& \left. \left. - \frac{2\beta_1^2}{\beta_0^3(6\beta_0+\lambda_+^z-\lambda_-^z)} \left(\frac{1}{L_0^3} - \frac{1}{L^3} \left(\frac{L_0}{L} \right)^{\delta^z} \right) \right] \right\} + (+ \leftrightarrow -), \quad (43)
\end{aligned}$$

where $\delta^z = (\lambda_+^z - \lambda_-^z)/2\beta_0$. Note that there is a typo in eq. (8.27) of ref. [12]. The prefactor $r_L^{-\lambda_-^z/\beta_0}$ should read $r_L^{+\lambda_-^z/\beta_0}$.
